SUMMARY – Robot-assisted brain tumor biopsy is becoming one of the most important innovative technologies in neurosurgical practice. The idea behind its engagement is to advance the safety and efficacy of the biopsy procedure, which is much in demand when planning the management of endocranial tumor pathology. Herein, we provide our earliest institutional experiences in utilizing this mesmerizing technology. Cranial robotic device was employed for stereotactic robot-assisted brain glioma biopsy in three consecutive patients from our series: an anaplastic isocitrate dehydrogenase (IDH) negative astrocytoma (WHO grade III) located in the right trigone region of the periventricular white matter; a low grade diffuse astrocytoma (WHO grade II) of bilateral thalamic region spreading into the right mesencephalic area; and an IDH-wildtype glioblastoma (WHO grade IV) of the right frontal lobe producing a contralateral midline shifting. Robot-assisted tumor biopsy was successfully performed to get tissue samples for histopathologic and immunohistochemical analysis. The adjacent tissue iatrogenic damage of the eloquent cortical areas was minimal, while the immediate postoperative recovery was satisfactory in all patients. In conclusion, considering the preliminary results of our early experiences, robot-assisted tumor biopsy was proven to be a feasible and accurate procedure when surgery for brain glioma was not an option. It may increase safety and precision, without expanding surgical time, being similarly effective when compared to standard stereotactic and manual biopsy. Using this method to provide accurate sampling for histopathologic and immunohistochemical analysis is a safe and easy way to determine management strategies and outcome of different types of brain glioma.

Key words: *Neurosurgery; Brain glioma; Robotics; Stereotactic biopsy*

Introduction

Robot-assisted neurosurgery is recently becoming one of the most important innovative technologies in

surgical practice. The idea behind its introduction is to further advance the safety, efficacy and precision of neurosurgical procedures, which are much in demand when dealing with endocranial tumor pathology, where management outcome of such a delicate process is concerned. The principal goal of this most modern technology is to supplement contemporary neurosurgical operative armamentarium with a safe device that may methodically enhance accuracy and precision in the operating room, which would not be possible

otherwise. Moreover, robotic biopsy also facilitates careful preoperative planning¹.

Topics in effective brain glioma surgery include determining the exact lesion location, and assuring optimal approach to the surgical target in relation to the patient's unique anatomy, enabling tumor resection with a high degree of accuracy and procedure control to minimize adjacent healthy brain tissue damage. That has been the aim of surgery ever since 1908, when Horsley and Clarke defined stereotactic calculation based on a coordinate system and created a frame fixed to the skull, which would accurately locate any intracranial point in three dimensions (3D)².

Frame-based stereotactic biopsy, as well as frameless image-guided one using scalp fiducial markers, have been considered the gold standard for brain biopsies regardless of their limitations associated with device flexibility, stability, accuracy, and biopsy needle positioning. Nonetheless, robot-assisted stereotactic biopsy could provide advantages over these two techniques avoiding their downside effects³. It exemplifies one of the earliest and finest uses of neurosurgical robotics being accepted by the scientific neurosurgical community in recent times⁴. It was initially employed in 1985 to perform stereotactic biopsy of a deep-seated brain lesion as the first-ever surgical robot procedure⁵. Since then, navigation and robotics in neurosurgery have improved very much, being successfully employed on a broader basis worldwide.

A robotic probe is the main tool for robot-assisted stereotactic tumor biopsy. It is interfaced with a computerized tomographic (CT) scanner and mounted at its end effector. Once the target is identified, a simple command moves the robot to a position pointing toward the target, which is a faster and more accurate procedure in comparison to the manually adjustable stereotactic frame biopsy. Appropriate preoperative imaging provides an anatomical roadmap to guide the biopsy needle to the exact target⁶. It is obvious that the above mentioned accuracy and safety, which is achieved by proper robot calibration, is the most essential benefit of such a procedure. Additionally, characteristics of robotic technology also include a combination of agility, robustness, resilience, and precision, which have been unseen previously.

A tendency of robot miniaturization, cost-effectiveness, mass production, and increasing procedure precision will distinguish prosperous robotic technolo-

gies of the future, which will advance modern neurosurgical practice even further⁷.

Herein, we provide preliminary results of our earliest institutional experiences in utilizing this mesmerizing technology for stereotactic biopsy of brain glioma, and evaluate the literature dealing with this most modern operative tool.

Illustrative Case Series

Medtronic Stealth Autoguide cranial robotic device was employed for stereotactic robot-assisted tumor biopsy in all patients from our series. All samples were positive for tumor tissue, which was sent for histopathologic and immunohistochemical (IMH) analysis. The adjacent brain tissue iatrogenic damage to the eloquent cortical areas was minimal, while the immediate postoperative recovery was satisfactory in all of them.

Case 1

A 74-year-old female patient was admitted to the hospital as an emergency due to a sudden attack of epileptic seizure experienced for the first time in her life. A left-sided moderate motor weakness was observed. She was referred to urgent contrast magnetic resonance imaging (MRI) of the brain, which revealed a space occupying, deep-seated, expansive tumor lesion in the right trigone region of the periventricular white matter with perifocal edema and compression of the occipital horn of the right lateral ventricle (Fig. 1 A-C).

She was scheduled for robot-assisted tumor biopsy *via* the right temporal gyrus incision, which was chosen as the safest optimal surgical approach. The exact tumor location, the trajectory and end point were determined by navigation system, and the robotic probe was mounted at its end effector and positioned pointing toward the target, allowing the robot to move on after receiving a simple command. Following trephination of the right temporal bone and cortical incision, five samples of the tumor tissue were collected by the robotic probe and sent for histopathologic and IMH examination identifying the tumor as an anaplastic, isocitrate dehydrogenase (IDH) negative astrocytoma (WHO grade III).

Immediate postoperative course and CT brain scanning were uneventful. Native postoperative brain

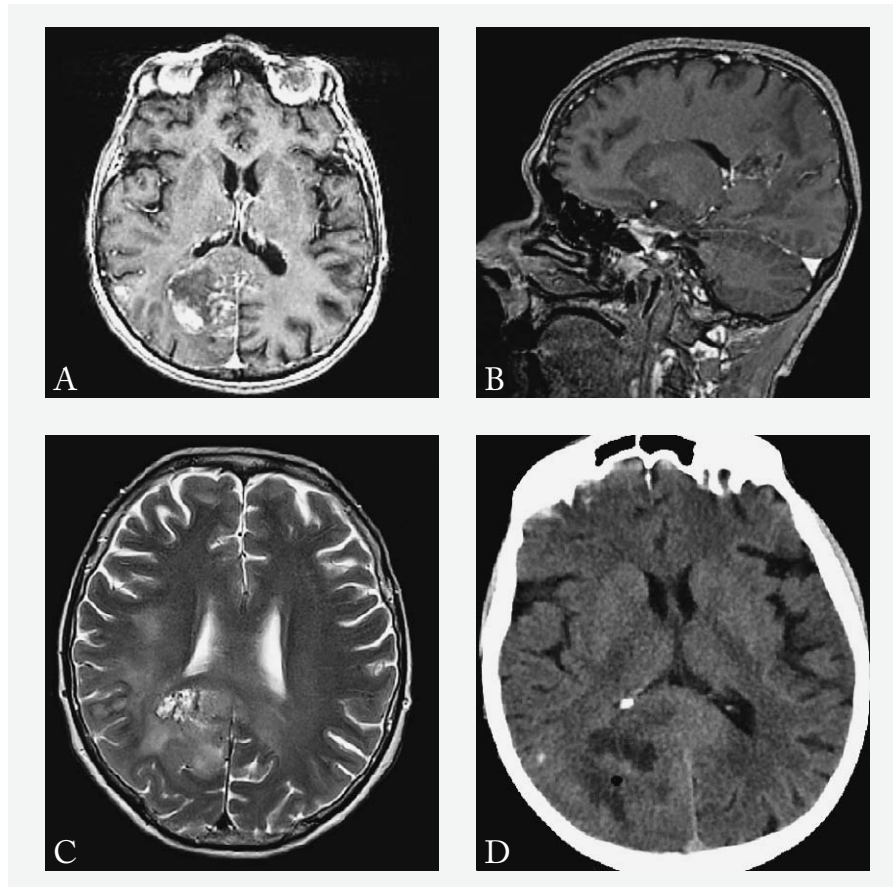

Fig. 1. Axial view of T1-weighted contrast-enhanced magnetic resonance imaging (MRI) of the brain revealing a space occupying, deep-seated, expansive tumor lesion in the right trigone region of the periventricular white matter (A); sagittal MRI reformation confirming the trigonal periventricular tumor (B); axial view of T2-weighted brain MRI depicting solid tumor lesion in the right trigone region with perifocal edema and compression of the occipital horn of the right lateral ventricle (C); native postoperative brain axial computed tomography (CT) scan identifying a drop of endocranial air at the site of tumor biopsy (D).

axial CT scan identified a drop of endocranial air at the site of tumor biopsy (Fig. 1 D).

The patient was discharged without progression of neurological deficit and with no seizures observed. Further oncologic treatment was advised, as well as physical therapy.

Case 2

A 66-year-old male patient presented with headache, dizziness, and mental disorientation having no major neurological deficit. Upon hospital admission, neuroradiology diagnostics was done. Native and contrast enhanced MRI depicted bilateral periventricular

thalamic mass lesions spreading into the right dorsal mesencephalic region and causing almost complete obstruction of the third ventricle and edema of the right temporal lobe (Fig. 2 A, B).

Robot-assisted tumor biopsy *via* the right parietal bone burr holing was performed. The precise tumor location, the trajectory, and entry and target points were defined using the neuronavigation system, and four samples of the tumor tissue were collected by the robotic probe *via* cortical incision. Two additional tissue samples were taken from a distance of 5 mm and 10 mm above the target point. Histopathologic and IMH examination identified the tumor as a low grade

Fig. 2. Native axial brain T1-weighted magnetic resonance imaging (MRI) depicting a periventricular mass lesion of the right thalamic region with compression of the third ventricle (A); contrast enhanced axial brain T1-weighted MRI depicting bilateral periventricular thalamic mass lesions spreading into the right dorsal mesencephalic region and causing almost complete obstruction of the third ventricle and edema of the right temporal lobe (B); native postoperative brain axial computed tomography scan detecting a globule of endocranial air at the tumor biopsy site (C).

Fig. 3. Contrast enhanced axial T1-weighted brain magnetic resonance imaging (MRI) revealing a parasagittal expansive, partially solid and partially cystic process of the right frontal lobe with a huge perifocal edema compressing frontal horn of the right lateral ventricle and producing contralateral midline shifting (A); coronal T1-weighted reformation of the brain MRI confirming a marked midline shift due to tumor enlargement (B); postoperative native axial computed tomography brain scan detecting a bubble of air at the location of tumor biopsy (C).

diffuse astrocytoma (WHO grade II) having low proliferative activity of tumor cells (Ki-67 2%). Native postoperative brain axial CT scan detected a globule of endocranial air at the tumor biopsy site (Fig. 2 C).

The patient was discharged from the hospital having minor motor weakness (hemiparesis) of the left limbs. Additional oncologic treatment and radiological follow-up at six months, as well as physical therapy were recommended.

Case 3

A 41-year-old male patient presented with heavy headaches but without neurological deficit. Contrast enhanced brain MRI revealed a parasagittal expansive, partially solid and partially cystic process of the right frontal lobe with a huge perifocal edema compressing frontal horn of the right lateral ventricle and producing contralateral midline shifting due to tumor enlargement (Fig. 3 A, B).

The right frontal bone burr holing was performed, followed by robot-assisted corticotomy and tumor biopsy. The neuronavigation system was employed for accurate tumor location, identifying the trajectory, as well as entry and target points. Four cylindrical tumor tissue samples were obtained using the robotic biopsy needle. The results of histopathologic and IMH analysis specified the tumor as an IDH-wildtype glioblastoma (WHO grade IV).

Postoperative native axial CT brain scan detected a bubble of air at the location of tumor biopsy (Fig. 3 C).

The patient was discharged from the hospital without neurological deficit. Supplementary oncologic treatment and early radiological follow-up at one month were required as obligatory.

Discussion

In this paper, we present the initial experiences of robot-assisted stereotactic tumor biopsy we have gained while treating selected brain glioma patients using a cranial robotic device and exemplifying the effectiveness of this technique.

Operational navigation systems in neurosurgery, combined with real-time microscopic visualization, have been developed and refined over the last three decades, continuing to evolve in precision, efficacy, and ergonomics ever since^{8,9}. For spatial registration of CT image data from fiducial markers on the scalp and their integration into the operating microscope, a specific computer-based system has been developed without requiring a stereotaxic frame¹⁰. Nevertheless, intraoperative MRI can also be used for stereotactic tumor biopsy in a regular neurosurgical operating environment¹¹. Nowadays, similar systems have gained a pivotal role during cranial and spinal surgeries to facilitate safer and more accurate, minimally invasive procedures, as well as to provide the best possible approaches and less time-consuming interventions¹². Hence, the majority of brain tumor biopsies are now executed using a frameless navigation-guided automated arm¹³.

Modern surgical navigation platforms are designed to be compatible with various intraoperative imaging modalities^{14,15}, to avoid possible disparity between the preoperatively acquired images and the intraoperative anatomy^{16,17}. Therefore, a rigid skull fixation robot-assisted stereotactic biopsy has gained prominence lately. Accordingly, we have recently tried such a technique in

three consecutive patients from our series who underwent brain glioma biopsy.

Anaplastic IDH negative astrocytoma was sequenced in the 74-year-old female patient with deep-seated tumor of the right trigone region. The isocitrate dehydrogenase mutation status has greater prognostic relevance than histologic diagnosis¹⁸, indicating that much of the poor prognostic significance of the advanced patient age is due to the absence of IDH mutations. Hence, patients with anaplastic gliomas harboring IDH mutations seem to fare much better than those without such a mutation in their tumors¹⁹.

Histopathologic and IMH sampling of tumor tissue in the 66-year-old male patient with bilateral periventricular thalamic mass spreading into the right dorsal mesencephalic region identified the tumor as a low grade diffuse astrocytoma. Proliferative activity of tumor cells assessed by the expression of Ki-67 nucleolar protein was 2%, indicating low activity and better prognosis. This protein has been widely used as a proliferation marker for human tumor cells for decades²⁰.

Histopathologic specimen and IMH analysis of a huge tumor of the right frontal lobe in the 41-year-old male patient specified the tumor as IDH-wildtype glioblastoma. The absence of IDH mutations indicated the most malignant glioma type (WHO grade IV), having the worst prognosis despite the patient's younger age. Although the IDH genes are mutated in the majority of grade II and III astrocytomas, they are rarely mutated in primary glioblastomas. Therefore, IDH status may unquestionably define biologically different subgroups of brain gliomas²¹, which is of great prognostic importance²², but also has a strong implication on therapeutic protocol selection.

Evaluating relevant literature, the efficacy of robot-assisted brain tumor biopsy, navigated neuroendoscopy, epilepsy electroencephalography (EEG) electrode placement, and ventricular catheter placement were confirmed²³⁻³¹. Robot-assisted procedures in children also appear to be feasible and safe, particularly for deep-seated tumors such as intrinsic pontine gliomas³²⁻³⁴. Such systems minimize movement and increase stability while bone drilling, perform accurate skin and cortical incision placement, and specify drilling depth based on measurement of the skull thickness, enabling real-time visualization³⁵. Several studies have reported a 95% up to 100% diagnostic accuracy from robot-assisted brain biopsy^{9,13,36}, resulting in con-

siderably lower target errors when compared to standard manual brain biopsy techniques³⁷, showing markedly shorter median surgical time, and evidently lower complication rates^{9,13,23,36-38}. Accordingly, all samples were positive for tumor tissue, the iatrogenic cortical damage was minimal, and no procedure-related short-term complications were recorded in the series of our patients.

Robots integrated with neuronavigation system and equipped with a specially designed artificial intelligence will probably become integral part of neurosurgical armamentarium in the near future, while telerobotics will enable remote performance of neurosurgical procedures at distant locations⁸. Hence, trends of growing in neurosurgical robotics are more likely to carry on further³⁹. However, since operational costs of robotic procedures are generally higher than customary neurosurgical methods³⁹, broader availability of this technology will remain questionable. Since the speed of the robotic movements is still relatively slow⁴⁰, it is another technical obstacle, which needs to be resolved before wider accessibility of such equipment is obtained.

In conclusion, according to our initial experiences and preliminary results, frameless robotic-assisted tumor biopsy technique seems to be a safe, accurate and feasible procedure when surgery for brain glioma is not an option. Such a technique may intensify precision without prolonging procedural time, being similarly operational when matched to the standard stereotactic and manual biopsy. Understanding tumor morbidity may also be enhanced by adopting this method, since providing accurate specimen for histopathologic and immunohistochemical analysis is a safe and easy way to determine management strategies and outcome of different types of brain glioma.

Supplementary clinical trials on a broader sample are essential to verify the safety and efficacy of the technique further.

Sažetak

SIGURNOST I UČINKOVITOST ROBOTOM POTPOMOŠNUTE STEREOTAKSIJSKE BIOPSIJE GLIOMSKIH TUMORA MOZGA: RANA INSTITUCIJSKA ISKUSTVA I VREDNOVANJE LITERATURE

K. Rotim, B. Splavski i F. Vrban

Robotom potpomognuta tumorska biopsija postaje jednom od najvažnijih inovativnih tehnologija u neurokirurškom radu. Razlog njezine uporabe nalazi se u daljnjem poboljšanju sigurnosti, učinkovitosti i preciznosti biopsijske metode koja je osobito značajna u planiranju opskrbe endokranijske tumorske patologije. Ovim radom donosimo prva institucijska iskustva u primjeni ove zašudne tehnologije pri biopsiji gliomskih tumora mozga. Kranijski robotički uređaj korišten je pri stereotaksijskoj robotom potpomognutoj tumorskoj biopsiji u tri susljedna slučaja iz naše serije, koja je uspješno učinjena radi uzimanja uzorka tumorskoga tkiva za patohistološku i imunohistokemijsku dijagnostiku u bolesnice s anaplastičkim izocitrat dehidrogenaza (IDH) negativnim astrocitomom (SZO st. III.) smještenim u periventrikulskoj bijeloj tvari desnoga trigonuma, u bolesnika s difuznim astrocitomom niskoga stupnja malignosti (SZO st. II.) smještenim obostrano u talamičkom području sa širenjem u desni mezencefalon, kao i u bolesnika s IDH-*wildtype* glioblastomom (SZO st. IV.) desnog čeonog režnja s pomakom središnjih tvorba. Jatrogena lezija pripadajućeg elokventnog moždanog korteksa bila je minimalna, dok je neposredni poslijeoperacijski oporavak bio uspješan u svih bolesnika. Uzimajući u obzir preliminarne rezultate našega početnog iskustva, zaključujemo kako je robotom potpomognuta tumorska biopsija dokazano izvodljiva i primjerena metoda u kirurgiji gliomskih tumora mozga kojom se može poboljšati sigurnost i preciznost bez produljenja vremena operacije, a koja je podjednako učinkovita u usporedbi sa standardnom stereotaksijskom i manualnom biopsijom. Uporaba navedene metode omogućuje precizno uzorkovanje tumorskoga tkiva za patohistološku i imunohistokemijsku analizu na siguran i lak način, što doprinosi odabiru strategije liječenja i predviđanju ishoda različitih tipova gliomskih tumora mozga.
